

Estimation methods of Adaptive Learning^{*}

Ajay Kirpekar [†]

September 28, 2020

Abstract

The paper examines the role of adaptive learning in a DSGE framework and compares the results between two popular approaches of estimating the Likely-hood function. The first approach uses conditional linearity and employs a Kalman filter to estimate the State Space model. The Second Approach take such nonlinearities in the stochastic dynamics into account and estimates the State Space Model via the Particle Filter with re-sampling. After Bayesian Estimation via Metropolis Algorithm, both models are compared after taking into account E-stability of beliefs assumed by model and compared through posterior inference and impulse responses.

[†]Fabio Milani has offered advice

1 Introduction

In the last few decades, much of the cyclical macroeconomic phenomena have been modeled through forward looking agents who form beliefs on macroeconomic variables. Very often, the popular convention is to solve these models with the assumption that agents are perfectly aware of all the relevant data at the current time period before forming expectations of the future¹. This assumption has been widely problematic with empirical literature (Lovell 1986, Evans Honkapohja 2001) and often cannot generate the persistence seen in the data.

In order to address a lack of persistence, researchers often employ habit formation ² as well as price indexation ³ to fit moments of output and inflation observed in the data. Milani(2004) employs habit formation and price indexation into a DSGE model and compares an adaptive learning framework to that of rational expectations and finds that learning offers a higher Marginal Likelihood ⁴.

However, when Adaptive learning via (Evans and Honkapohja 2001) is used to model expectations, traditional Kalman filters methods mis-specify the Likelyhood function that is used in posterior sampling. In order to account for nonlinearity in the Likelyhood function, this paper uses a particle filter via resampling (Villaverde and Rubio-Ramirez 2006). After accounting for both Likelyhood functions, I evaluate differences in: Posterior Distribution, Impulse Responses, State dynamics of beliefs.

By assuming agents follow a model via adaptive learning, agents form beliefs that are updated every period based on their accuracy to the data formed by the true data generating process. One question of interest is whether this process of formation of beliefs converges to the true data generating process (See Evans Hankapohja 2001), this convergence is coined the E-stability principle. A given set of parameters in a model are called "E-stable" if they lead agents to eventually form beliefs that exactly fit the inherent process of the underlying

⁴Geweke's Modified Harmonic Mean was used in order to adress the variation of this statistic

state dynamics. The paper compares the results between the parameters estimated from the Likelihood function via particle filter and that of the conditionally Linear Kalman filter.

2 Preliminary Model

This paper first investigates the standard differences highlighted in the baseline NK model. Presented below are the dynamic equations which are augmented with an adaptive learning framework. The reason for the initial specification is to exploit the nature of its properties as expressed by Bullard and Mitra (2002).

Given the *actual law of motion*:

$$(1) x_t = E_t[x_{t+1}] - \sigma^{-1}(i_t - r_t^n - E_t[\pi_{t+1}])$$

$$(2) \pi_t = kx_t + \beta E_t[\pi_{t+1}]$$

$$(3) i_t = \phi_x x_t + \phi_\pi \pi_t$$

$$(4) r_t^n = p_r r_{t-1}^n + \epsilon_t \sim N(0, \sigma_r^2)$$

where: x_t, π_t, i_t are Output gap, Inflation, and the Federal funds rate respectively.

In the following model, agents hold the following *perceived law of motion*:

$$(5) Z_t = \Lambda_{0,t} + \Lambda_{1,t}Z_{t-1} + \Lambda_{2,t}r_t^n + \eta_t, \text{ where: } \eta_t \sim N(0, 1)$$

$$\text{hence: } (7) E_t[Z_{t+1}] = \Lambda_{0,t} + \Lambda_{1,t}(\Lambda_{0,t} + \Lambda_{1,t}Z_{t-1} + \Lambda_{2,t}r_t^n) + \Lambda_{2,t}r_t^n$$

where: $Z_t = [x_t^*, \pi_t^*, i_t^*]'$ and $\Lambda_{i,t}$ represents the beliefs that are revised over time

$$(8) \phi_t = \text{vec}(\Lambda_{0,t}, \Lambda_{1,t}, \Lambda_{2,t})$$

$$(9) \phi_t = \phi_{t-1} - gR_t^{-1}X_t(y_t - X_t\phi_t)$$

$$(10) R_t = R_{t-1} - g(R_t^{-1} - X_t'X_t)$$

Where: $y_t = [x_t, \pi_t, i_t]'$ and: $X_t\phi_t = Z_t$

In the following standard setup, notice in equation (7) how agents, when forecasting variables in the future, observe shocks at time t , but do not observe the macroeconomic variables at time t . This aspect of observation demonstrates a crucial component of persistence gener-

ated in the standard NK model. Further more, Equations (9) and (10) are the recursive least squares procedure agents are assumed to follow when the update beliefs when forming expectations in time $t+2$. Equations (1)-(3) are labeled the "actual law of motion" as to indicate the true data generating process. While Equation (4) is considered the "percieved law of motion", so as to indicate agents perception of the how the Economy behaves. The system of Equations (1)-(7) is considered to be E-stable if:

$\lim_{t \rightarrow \infty} \phi_t = A^*$ Where A^* Represents the parameters that govern Equations(1)-(3) in matrix form.

In Models with Rational Expectations, it is often assumed that the parameters of interest are those that lead to a unique and stable equilibrium, otherwise known as a determinate solution. The notion of E-stability, like that of Determinacy, is also dependent upon the parameters of the model. In thier seminal work, Bullard and Mitra(2002) derived the property that in the standard NK model, conditions for E-stability and determinacy yield are one in the same.

The parameters that govern equations (1) -(3) are **both** Determinate and E-stable if:

$\phi_\pi + \phi_x \frac{(1-\beta)}{k} > 1$ Note: In models with more parameters or a different specification, it is more likely the case that E-stability and Determinacy conditions are not only different, but do not jointly apply.⁵

In order to test plausibility of learning in a standard NK model, I estimate the posterior distribution of θ , the structural parameters in equations (1)-(5). Using quarterly data from 1954-2019 for output gap, inflation, and the federal funds rate, I estimate θ using a Random Walk Metropolis Hastings Algorithm.

3 Constant Gain Learning:

In traditional models with learning, agents update beliefs in such a way that over time the changes in beliefs converges to 0. This means that agents dramatically update beliefs in

⁵Mclung 2020 offers an alternative specification which demonstrates this.

earlier periods, and as time goes on, the changes to their belief parameters become incrementally smaller. In light of evidence by Branch and Evans(2005) as well as Orphanides and Williams (2004), Takes more seriously, the view that agents update beliefs each period with equal weight. This constant gain parameter g , determines the degree to which agents update beliefs based on forecast errors. Throughout the paper, this parameter is the subject of key interest in the proceeding sections.

4 Estimation Procedure

In most models with bayesian learning, most researchers take the critical stance of assuming Gaussian normality⁶. That is, they assume that conditional on the previous states, the expected value of the next state follows a normal distribution. By utilizing Gaussian Normality, Kalman filter methods can be used to estimate the state space and therefore the likelihood function. Such assumptions take the critical stance that the learning parameters are fixed at each time period and do not follow a distribution of their own. In the preliminary NK model, this appears as:

$$(1a) Y_{obs,t} = \Gamma_0 S_t + \Gamma_1 S_{t-1} + \epsilon_t^m, \epsilon_t^m \sim N(0, I_3)$$

$$S_t = A_0 + A_1 S_t + A_2 E_t[S_{t+1}] + \nu_t$$

$$S_t = C_0 + C_1 E_t[S_{t+1}] + \eta_t, \eta_t \sim N(0, V_s)$$

After substituting for the expectation (7) we get:

$$(1b) S_t = \Lambda_{0,t} + C_1 P(\Lambda_{0,t} + \Lambda_{1,t} S_{t-1} + \Lambda_{2,t} r_t^n) + \eta_t, \text{where: } \Lambda_{i,t} \text{ are given by (9)-(10)}$$

After some manipulation, the P matrix which performs $T: \mathbb{R}^3 \rightarrow \mathbb{R}^5$ and S_t becomes:

$$(1c) S_t = L_{0,t} + L_{1,t} S_{t-1} + L_{2,t} n_t, n_t \sim N(0, V_s)$$

Where: $S_t = [x_t, \pi_t, i_t, r_t]'$, and $Y_{obs,t} = [GDP_t - GDP_{Potential,t}, Inflation_t, FFR_t]$.

After obtaining (1a),(1c), and given a specified Prior distribution. I am now able to estimate

⁶See: Milani 2002, Hommes, MavroMatris, Ozden(2018)

the Posterior distribution Where: $f(\theta|S_t, Y_t) \propto f(\theta)f(Y_t, S_t|\theta)$ and the Likelyhood is derived: $f(Y_t, S_t|\theta) = f(Y_t|S_t, \theta)f(S_t|S_{t-1}, \theta) \dots f(S_1|S_0, \theta)$. Using the following specification, I compare the Posterior distribution and Marginal Likelyhood to the traditional New Keynesian model using the Likelyhood generated through solving the Linear Rational Expectations Equilibrium of (1)-(4) via Gensys.⁷

5 Kalman/REE Results:

6 Likelyhood Misspecification :

As expressed earlier, When estimating models with Bayesian Learning, it is commonplace to treat the learning parameters as constants. In reality, this assumption comes with Misspecification issues. We know from the model, that the parameters, since they are endogenous to the states of the economy, should, in reality, be considered states themselves. Given this is the appropriate treatment, the traditional Kalman filter estimation can no longer be used. Referring back to the learning parameters, this becomes more clear.

$$\phi_t = \phi_{t-1} - gR_t^{-1}X_t(y_t - X_t\phi_t) , R_t = R_{t-1} - g(R_t^{-1} - X_t'X_t) \text{ and, } X_t = h(S_t, S_{t-1}). \text{So, } \phi_t = h_1(S_t, S_{t-1}) \text{ and, } R_t = h_2(S_t, S_{t-1})$$

where h_1 and h_2 are **nonlinear matrix functions**. We know the Likelyhood is derived from:

$$(11) f(Y_t, S_t|\theta) = f(Y_t|S_t, \theta)f(S_t|S_{t-1}, \theta) \dots f(S_1|S_0, \theta).$$

$$(12) f(Y_t, S_t|\theta) = f(Y_t|S_t, \theta, \phi_t, R_t, \theta) \dots f(S_1|S_0, \phi_1, R_1, \theta).$$

$$(13) f(Y_t, S_t|\theta) = f(Y_t|S_t, \theta, \phi_t, R_t, \theta) \dots f(S_1|S_0, h_1(S_1, S_0), h_2(S_1, S_0), \theta, \phi_1, R_1, \theta).$$

In the Linear representation presented in Section 2, (11) is equivalent to (12). After substituting the learning process, (12) is indeed equivalent to (13). Since (13) is intractable, this representation is flawed and leads to erroneous values of S_t , meaning that the model

⁷This exercise is also done in Milani(2002).

ultimately yields a misspecified Likelihood function. In order to properly characterize the New Keynesian model with an Adaptive Learning framework, we must depart from a conditionally Gaussian framework, append the state variable S_t with the learning parameters, and estimate using particle filter methods.

7 Particle Filter:

With similar motivations as *Rubio-Ramirez & Villaverde(2007)* and *Herbst & Schorfheidi(2017)*, I seek to estimate a nonlinear state space system via a particle filter with a re-sampling procedure. In essence, I express the learning parameters ϕ_t and R_t as state variables(rather than take them as given) in order to obtain the "correct" estimate of the Likelihood function. The Economic meaning behind estimating the learning parameters as states can interpreted in the following way: When agents form expectations of the future, the stochastic processes which drive macroeconomic variables are characterized by distributions that follow a mean and variance. Though the shocks are independent of the macroeconomy, the distribution macroeconomic variables as well as the learning parameters are endogenous to one another. By adapting the learning parameters as part of the state variable, the researcher is in effect taking the stance that the distribution of macro variables is dependent on the distribution of beliefs and vis versa. Notice ,However, in the conditionally linear model, since we hold the learning parameters ϕ_t and R_t fixed, we assume that beliefs are driven by macro variables but not the reverse. The Particle Filter in essence simulates the stochastic error terms with a sufficient number of draws, places weights on the realized number states,and calculates the a weighted likelihood. Often this procedure places high weight on few particles and 0 weight on most particles which in essence induces a high variance of the likelihood function.⁸ In order to avoid this issue, I follow *Rubio-Ramirez Villaverde(2007)* with the following algorithm.⁹

⁸See..blah blah blah

⁹For Convergence properties of the Likelihood, please refer to *Rubio-Ramirez Villaverde(2007)* and *Kitigawa....*

$$(14) Y_t = M_1 S_t + M_2 S_{t-1} + \epsilon_t^m.$$

$$(15) S_t = f(S_t, \epsilon_t^s).$$

Step 1(Initialize): Set $e_t^j \sim \epsilon_t^s$.

Step 2(Propagate): $S_t^j = f(S_{t-1}^j, \epsilon_t^j)$.

Step 3(Evaluate): $w_t^j = \frac{L(Y_t, S_t^j)}{\sum w_t^i}$. Where $L(Y_t, S_t^j)$ is the Likelihood function obtained from (14).

Step 4(Resample): $q_i \sim w_{t0}^j$ and set: $S_{t|t-1}^j = S_t^i$, for all $\{q_i\}_{i=0}^J$

Set $t = t+1$; and repeat till $t = T$.

Step 5(Calculate Likelihood): $P(Y^T, \theta) \approx \frac{1}{J^2} \left(\prod_{t=1}^T \left(\sum_{j=1}^J p(Y_t | w_t^j, S_{t|t-1}^j, Y^{t-1}; \theta) \right) \right)$.

Where $P(Y^T, \theta)$ is obtained from measurement equation(14).

With the stated procedure, as the number of particles, J becomes greater, the likelihood becomes converges to the true distribution. However, because one must keep track of the states and thier relative values across the sample, there exists a tradeoff between and accuracy and computational time of the algorithm. In this paper, I find that the results of estimation do not change much between 10 - 100 thousand particles. Hence I assume J to be 100 thousand, a sufficient approximation to the true likelihood function of interest in the proceeding results. Additionally, because the likelihood function in the conditionally linear case is indeed subject to misspecification, as seen in (13). We know traditional measures of fit via marginal Likelihood are not an appropriate comparison of model fit with finite sample size. Because of this reason, other standard measures of model fit may be more appropriate such as MSE or RMSE.¹⁰

¹⁰show some evidence with similar model comparison particle filter.

8 Particle Filter Results:

As mentioned earlier, in this paper, I append S_t to include ϕ_t, R_t as well as the macro-variables from (1)-(4). With the following equations, I am now able to estimate the Likelihood function with non-linearity taken into account and proceed with a Particle Filter Metropolis-Hastings procedure. the following procedure, follows the same RWMH algorithm, but instead calculates the log-likelihood using the particle filter method expressed in the previous section and then proceeds to calculate the log-posterior.

9 Hybrid NK Model:

Though the preliminary model offers interesting considerations regarding the the role of learning, it is also important to compare differences in estimation in a more robust New Keynesian model. That is, one that accounts for habits, inflation indexation, and a lagged interest rate rule.¹¹ This paper appends the preliminary with a more comprehensive model that attributes persistence in inflation and output to price indexation on the part of firms and habit formation of households respectively. On the part of firms, follow Gali(2008) , and attribute their marginal cost proportional to parameters of the production and labor demand.

Households:

First, I assume households have the choice to consume from a basket of goods, offered by a continuum of firms and that their preferences between differing goods follows Dixit-Stiglitz Preferences.¹²

$C_t = \int_0^1 (c_t(i))^{\frac{\epsilon}{\epsilon-1}} di)^{\frac{\epsilon-1}{\epsilon}}$. It can be shown that the price of the optimal consumption bundle can be expressed s.t.

$$P_t C_t = \int_0^1 p_t(i) c_t(i) di \quad \text{where, } P_t \equiv \left(\int_0^1 p_t(i)^{\frac{\epsilon}{\epsilon-1}} di \right)^{\frac{\epsilon-1}{\epsilon}}$$

¹¹See: CEE,.....

¹²cite Dixit Stiglitz

$U(C_t, L_t) = \frac{(C_t - hC_{t-1})^{1-\sigma}}{1-\sigma} - \frac{L_t^{1+\psi}}{1+\psi}$ while the household budget constraint is:

$$P_t C_t + B_t = L_t w_t + (1 + i_{t-1}) B_{t-1}$$

after taking the first order conditions, log-linearizing near the steady state, and using market clearing conditions ($c_t = y_t$), the following holds:

$$y_t = w_1 E_t y_{t+1} + w_2 (E_t \pi_{t+1} - i_t) + w_3 E_t y_{t+2} + w_4 y_{t-1}.$$

After plugging for the natural rate of output (where y_t^n is the output when $\pi_t = 0$):

$$(1c) \ x_t = w_1 E_t x_{t+1} + w_2 (E_t \pi_{t+1} - i_t - r_t^n) + w_3 E_t x_{t+2} + w_4 x_{t-1}.$$

$$r_t^n = p_r r_{t-1}^n + \epsilon_t^r, \epsilon_t^r \sim N(0, \sigma_r^2)$$

where x_t is the deviation of output to the natural rate of output, and r_t^n is considered the natural rate of interest.¹³

Firms:

On the firm side, I assume that firms operate in a monopolistically competitive environment and seek to maximize:

$$\max_{p_t^*(j)} E_t [\sum_{k=t}^T \theta^k Q_{t,t+k} \Pi_{t+k}]$$

$$\Pi_t \equiv y_{t+k}(j) p_t^*(j) - f^{-1}(y_{t+k}) \text{ and } Q_{t,t+k} = \beta^k \frac{P_t}{P_{t+k}} \left(\frac{\lambda_{t+k}}{\lambda_t} \right)$$

In the firm's optimization problem, they seek to maximize via standard Calvo pricing framework where they take into account, $Q_{t,t+k}$, their stochastic discount factor which is expressed as the ratio of marginal utility that comes from the household's Lagrange multiplier via the intertemporal margin of consumption. Following CEE¹⁴ and Gali(2008)¹⁵, I assume agents who are unable to optimize next period, index their prices partially (by γ) to observed inflation in the previous time period. By doing so, I am able to express Π_{t+k} as:

$$\Pi_t \equiv Y_{t+k} p_t^*(j) \left(\frac{p_t^*(j) \pi_{t+k-1}^\gamma}{P_t} \right)^{-\epsilon} - w_{t+k} f^{-1} \left(\left(\frac{p_t^*(j) \pi_{t+k-1}^\gamma}{P_t} \right)^{-\epsilon} Y_{t+k} \right) \text{ We assume that firms produce}$$

¹³for simplicity in the estimation, I generalize r_t^n as an AR(1) process, similar to Milani(2002)

¹⁴Christiano, Eichenbaum, Evans(2005)

¹⁵Monetary Policy, Inflation, and the Business Cycle(2008)

with the same production function:

$$Y_t(i) = f(L_t(i)) \equiv A_t L_t(i)^{1-\alpha} \text{ Note:}$$

$$f^{-1}(x) \equiv x^{\frac{1}{1-\alpha}} \text{ represents the labor demand function}$$

After taking the first order condition, substituting for the wage, and log-linearizing around a 0 inflation steady state, I obtain the following Phillips curve:

$$(2c)\pi_t = \eta_1 x_t + \eta_2 x_{t-1} + \eta_3 E_t[x_{t+1}] + \eta_4 E_t[\pi_{t+1}] + \eta_5 \pi_{t-1} + u_t$$

$$u_t = p_u u_{t-1} + \epsilon_t^u; \epsilon_t^u \sim N(0, (\sigma_t^u)^2)$$

Details of this derivation can be found in the Appendix.

Monetary Policy:

I assume that Monetary Policy targets the FFR using the following rule:

$$(3c)i_t = \rho i_{t-1} + (1 - \rho)(\phi_x x_t + \phi_\pi \pi_t) + \epsilon_t^i$$

$$\epsilon_t^i \sim N(0, (\sigma_t^e)^2)$$

Taken together, the full model(1c-3c) now depicts a New Keynesian model with persistence driven by both real economic variables as well as expectations driven persistence. Hence, I am able to express the dynamics of the stated model in Matrix form:

$$(4c)Z_t = AZ_{t-1} + BU_t + CE_t[Z_{t+1}] + DE_t[Z_{t+2}] + E\nu_t$$

$$\text{where: } \nu_t \sim N(0, \Sigma_t) \quad Z_t = [x_t, \pi_t, i_t] \quad U_{t-1} = [u_{t-1}, r_{t-1}^n]$$

and Σ_t is endogenous to the variances from the cost push, natural rate, and monetary policy shocks($\sigma_r^2, \sigma_e^2, \sigma_u^2$). Unlike the preliminary model, the Hybrid NK model accounts for two period ahead forecasts on the part of agents and thus further propagates nonlinearity with cubed terms in the learning parameters agents form for macro variables. This can be seen if one substitutes (5c) and (6c) into (4c). As nonlinearity becomes more pronounced, the differences in estimation also become more apparent.

$$E_t Z_t = \Lambda_{0,t} + \Lambda_{1,t} Z_{t-1} + \Lambda_{2,t} U_t$$

$$E_t Z_{t+1} = \Lambda_{0,t} + \Lambda_{1,t} E_t Z_t + \Lambda_{2,t} R U_t$$

$$(5c) E_t Z_{t+1} = \Lambda_{0,t} + \Lambda_{1,t}(\Lambda_{0,t} + \Lambda_{1,t} Z_{t-1} + \Lambda_{2,t} R U_t) + \Lambda_{2,t} R U_t$$

$$(6c) \ E_t Z_{t+2} = \Lambda_{0,t} + \Lambda_{1,t} E_t Z_{t+1} + \Lambda_{2,t} R^2 U_t$$

Using the same methodology discussed earlier, (4c) is then cast into state space form and becomes: $(7c) Z_t = L_{0,t} + L_{1,t} Z_{t-1} + \epsilon_t^s$, $\epsilon_t \sim N(0, A_t)$

Thus when comparing the Particle filter to the Conditionally linear Kalman filter, The inherent difference comes from whether or not to append Z_t with ϕ_t and R_t , the adaptive learning parameters. The next section discusses the results post estimation.

10 Hybrid NK results:

In the Estimation phase, This paper takes the state space form of (7c) and compares the posterior distribution of the parameters that govern the law of motion. For the purposes of tractability and clarity, I only consider parameters that yield a unique and stable Rational expectations equilibrium for equation (4c). If a draw from the proposal distribution offers an indeterminate solution, it is dropped and the MCMC algorithm continues to draw from the proposal distribution till there is a REE.

A note on Projection Facilities: It is well known in the Literature that often initial conditions or a set of realized shocks can lead to unstable beliefs that diverge to a stationary solution. (Marcet and Seargent 1989) In the context of the Hybrid NK model, this become a point of concern when lags attributed to the actual law of motion can induce unstable beliefs. In order to avoid these phenomena, I take the stance that agents recenter thier beliefs somewhere near the REE of the Eigenvalues inherent in the Actual Law of Motion: $\phi_t \sim N(\phi^*, I)$ if $|eig(L_{1,t})| > 1$.

11 E-stability:

In the preliminary model, conditions for E-stability and Determinacy are one in the same. However, in the Hybrid NK model, conditions for E-stability and Determinacy are different.

Thus there are a variety of cases where parameters can be: 1.Establish/determinate 2.Unstable/determinate 3.Unstable/indeterminate 4. Establish/indeterminate. This section describes the conditions as provided by Evans and Honkapohja(2012) in greater detail, and seeks to highlight the Economic significance of these principles. In a general framework this can be expressed as:

$$\text{ALM: } x_t = Ax_{t-1} + BE_t[x_{t+1}] + CU_t$$

$$\text{PLM: } x_t = L_0x_{t-1} + L_1U_t + \eta_t$$

$$\text{Stationary Shocks: } U_t = RU_{t-1} + \epsilon_t$$

After plugging in the Perceived law of motion(PLM) into the Actual law of motion(ALM) and simplifying:

$$x_t = C_1x_{t-1} + C_2U_t, \text{ where: } C_1 \equiv (A + BL_0L_0) \text{ and } C_2 \equiv B(L_0L_1 + L_1R) + C.$$

A model where agents hold beliefs such that: $L_0^* = C_1$ and $L_1^* = C_2$ are labeled a rational expectations equilibrium because the beliefs they form exactly match the equilibrium ALM. However, if we relax this assumption and allow agents divert off the equilibrium path with recursive learning, we cannot guarantee that the parameters that make up the model will always lead to $\lim_{t \rightarrow \infty} L_{0,t} = C_1 = L_0^*$ and $\lim_{t \rightarrow \infty} L_{1,t} = C_2 = L_1^*$. As per Evans and Honkapohja, the E-stability condition is then satisfied if: $Dh(\theta)$ contains negative eigenvalues. Where $h(\theta) = \lim_{t \rightarrow \infty} E[Q(t, \theta, Z_t(\theta))]$ and $\theta_t = \theta_{t-1} + gQ(t, \theta_{t-1}, Z_t)$. Here, θ_t represents the belief parameters of L_0 and L_1 . While Z_t represents the corresponding information used to form the PLM¹⁶ and $Q(t, \theta, Z_t(\theta))$ is the forecast error of the agent. With respect to the above model, this condition is satisfied when:

$$h_1(\theta) = C_1 - L_0$$

$$h_2(\theta) = C_2 - L_1$$

¹⁶For more details on the stability of beliefs, see Evans and Honkapohja(2012)

$$\text{Dh}(\theta) = \begin{bmatrix} \frac{\partial h_1}{\partial L_0} & \frac{\partial h_1}{\partial L_1} \\ \frac{\partial h_2}{\partial L_0} & \frac{\partial h_2}{\partial L_1} \end{bmatrix}_{L_0=L_0^*, L_1=L_1^*} \text{ contains negative real eigenvalues.}^{17}$$

In the next section, the paper takes the posterior parameter draws from the previous estimation and filters them for those which are E-stable. Thus the results show the parameters which are both Determinate and E-stable in the Hybrid NK model.¹⁸

12 Results for E-stability:

¹⁷For another implementation of E-stability, refer to McClung(2020)

¹⁸See Appendix for E-stability conditions of the Hybrid NK model.

Appendix A. Investment Spending Curve

Households seek to maximize:

$$E_t[\sum_{t+k}^T \beta^k U(C_{t+k}, L_{t+k})] \text{ s.t } P_{t+k}C_{t+k} + B_t = L_{t+k}w_{t+k} + (1 + R_{t+k-1})B_{t+k-1} \text{ for } k=1,2,\dots,T$$

This becomes, $\mathcal{L} = E_t[\sum_{t+k}^T \beta^{t+k} U(C_{t+k}, L_{t+k}) - \lambda_{t+k}(P_{t+k}C_{t+k} + B_t - L_{t+k}w_{t+k} - (1 + R_{t+k-1})B_{t+k-1})]$

$$(1) \quad \frac{\partial \mathcal{L}}{\partial C_t} = (C_t - hC_{t-1})^{-\sigma} - h\beta(E_t C_{t+1} - hC_t) - \lambda_t P_t = 0$$

$$(2) \quad \frac{\partial \mathcal{L}}{\partial L_t} = -(L_t)^\psi + \lambda_t(w_t) = 0$$

$$(3) \quad \frac{\partial \mathcal{L}}{\partial B_t} = -\lambda_t + E_t[\lambda_{t+1}](1 + R_t) = 0$$

After Substitution of (1) in (3):

$$E_t\left[\frac{(C_{t+1}-hC_t)^{-\sigma}-h\beta(C_{t+2}-hC_{t+1})}{(C_t-hC_{t-1})^{-\sigma}-h\beta(C_{t+1}-hC_t)} \frac{P_t}{P_{t+1}}\right] = (1 + R_t)^{-1}$$

After Log Linearization around the S.S. and setting $c_t = y_t$:

$$y_t = w_1 E_t y_{t+1} + w_2 (E_t \pi_{t+1} - i_t) + w_3 E_t y_{t+2} + w_4 y_{t-1}. \text{ Where:}$$

$$i_t = \log(R_t) - \log(R)$$

$$w_1 \equiv \left[\frac{1+h^2\beta+h\beta}{1+h+h^2\beta} \right]$$

$$w_2 \equiv \left[\frac{(1-h)(1-h\beta)}{\sigma(1+h+h^2\beta)} \right]$$

$$w_3 \equiv \left[\frac{-h\beta}{1+h+h^2\beta} \right]$$

$$w_4 \equiv \left[\frac{h}{1+h+h^2\beta} \right]$$

using the fact that $x_t = y_t - y_t^f$ and $y_t^f = w_1 E_t y_{t+1}^f + w_2 (-i_t) + w_3 E_t y_{t+2}^f + w_4 y_{t-1}^f$,

we can express the IS curve as: $x_t = w_1 E_t x_{t+1} + w_2 (E_t \pi_{t+1} - i_t - r_t^n) + w_3 E_t x_{t+2} + w_4 x_{t-1}$.

where $r_t^n = \frac{1}{w_2} (-y_t^f + y_{t+1}^f + w_3 y_{t+2}^f + w_4 y_{t-1}^f)$.

Appendix B. Phillips Curve

Firms seek to maximize the following objective function:

$$\mathcal{V} = \max_{p_t^*(j)} E_t[\sum_{k=t}^T \theta^k Q_{t,t+k} \Pi_{t+k}]$$

$$\Pi_t \equiv y_{t+k}(j)p_t^*(j) - f^{-1}(y_{t+k}) \text{ and } Q_{t,t+k} = \beta^k \left(\frac{P_t}{P_{t+k}} \right) \left(\frac{\lambda_{t+k}}{\lambda_t} \right)$$

$$\frac{\partial \mathcal{V}}{\partial p_t^*(j)} = E_t[\sum_{k=t}^T \theta^k \beta^k \left(\frac{\lambda_{t+k}}{\lambda_t} \right) \left(\frac{p_t^*}{p_{t+k}} \right) \left(\frac{\pi_{t+k-1}^\gamma p_t^*}{p_{t+k}} \right)^{-\epsilon} (Y_{t+k}) - f^{-1} \left(\left(\frac{\pi_{t+k-1}^\gamma p_t^*}{p_{t+k}} \right)^{-\epsilon} (Y_{t+k}) \right) \left(\frac{w_{t+k}}{p_{t+k}} \right)] = 0$$

Note: Using the labor supply condition and the production function of the firms, the real wage can be expressed in terms of λ_t .

$$L_t^\psi = \left(\frac{\lambda_t}{P_t}\right)w_t$$

$$w_t = MPL = \frac{\partial(N_t^{1-\alpha})}{\partial N_t}w_t = c_2\lambda_t.$$

$$\text{where, } c_2 \equiv \frac{\psi}{\alpha+\psi}.$$

After Log-Linearizing around a 0 Inflation S.S, the FOC becomes :

$$p_t^* = \frac{1-\beta\theta}{1+\psi\epsilon}[-c_2\lambda_t - \gamma\epsilon\psi\pi_{t-1} + \psi y_{t+k} + \Sigma(\beta\theta)^k(-c_2\lambda_{t+k} - \gamma\epsilon\psi\pi_{t+k-1} + \psi y_{t+k})] + (1-\beta\theta)\Sigma p_{t+k}(\beta\theta)^k. (*)$$

Using the formula for aggregate price as a function of the optimal price by optimizing firms and the previous price:¹⁹ $P_t = [(p_t^*)^{-\epsilon}(1-\theta) + (P_{t-1}\pi_{t-1}^\gamma)^{1-\epsilon}\theta]$

we get the Phillips curve:

$$\pi_t = \eta_1 x_t + \eta_2 x_{t-1} + \eta_3 E_t[x_{t+1}] + \eta_4 E_t[\pi_{t+1}] + \eta_5 \pi_{t-1} + u_t^{20}$$

$$\eta_1 \equiv [kc_2c_1 + kh_1^2c_2 + k\psi]$$

$$\eta_2 \equiv [-khc_2c_1]$$

$$\eta_3 \equiv [-kh\beta c_1c_2]$$

$$\eta_4 \equiv \frac{\beta}{1+\gamma\beta\theta}$$

$$\eta_5 \equiv \left[\frac{\gamma}{1+\gamma\beta\theta} - \gamma\epsilon\psi k\right]$$

$$c_1 \equiv \left(\frac{-\sigma}{1-h\beta}\right)\left(\frac{1}{1-h}\right)$$

Using flexible prices, we know we are able to express λ_{t+k} in terms of x_t .

Under flexible prices, we know $\theta = 0$ and $P_{t+k} = p_t^*$ Which yields: $c_2\lambda_{t+k}^f = \psi y_{t+k}^f$.

Using the log linearized FOC, we can express (*) in terms of x_t by using the fact that:

$\lambda_t = \lambda_t^x - \lambda_t^f$. Where superscript f denotes the flexible price equilibrium output, and superscript x denotes the terms in λ_t as x_t .

¹⁹for ease of notation, all of the variables in the following lines are "hatted" \hat{a}_t , and are their respective log linearized values.

²⁰here, we add cost push shocks to the Phillips curve

Appendix C. E-stability Condition

The Equations in the Hybrid NK model(4c) are considered the ALM(actual law of motion) while the PLM(percieved law of motion) which agents use is:

$$Z_t = \Lambda_{t,0} + \Lambda_{t,1}Z_{t-1} + \Lambda_{t,2}Z_{t-1}$$

$$E_t[Z_{t+1}] = \Lambda_{t,0} + \Lambda_{t,0}\Lambda_{t,1} + \Lambda_{t,1}^2 Z_{t-1} + (\Lambda_{t,1}\Lambda_{t,2} + \Lambda_{t,2}R)U_t$$

$$E_t[Z_{t+2}] = (\Lambda_{t,0} + \Lambda_{t,0}\Lambda_{t,1} + \Lambda_{t,1}\Lambda_{t,0}\Lambda_{t,1}) + \Lambda_{t,1}^3 Z_{t-1} + [\Lambda_{t,1}(\Lambda_{t,1}\Lambda_{t,2} + \Lambda_{t,2}R) + \Lambda_{2,t}RR]U_t$$

plugging the expectation terms into the ALM from (4c) gives the result:

$$Z_t = \Omega_0 + \Omega_1 Z_{t-1} + \Omega_2 U_t + E\nu_t$$

$$\Omega_0 \equiv (CV_0^1 + DV_0^2) \quad \Omega_1 \equiv (A + CV_1^1 + DV_1^2) \quad \Omega_2 \equiv (B + CV_2^1 + DV_2^2).$$

$$\text{where } V_1^1 \equiv \Lambda_1^2, V_1^2 \equiv \Lambda_1^3, V_0^1 \equiv \Lambda_0 + \Lambda_0\Lambda_1, V_0^2 \equiv \Lambda_0 + \Lambda_1\Lambda_0 + \Lambda_1\Lambda_0\Lambda_1$$

$$\text{and } V_2^1 = \Lambda_1\Lambda_2 + \Lambda_2R, V_2^2 = \Lambda_1[\Lambda_1\Lambda_2 + \Lambda_2R] + \Lambda_2R^2$$

Hence , we can express the Mapping between the ALM and the PLM as:

$$h(\theta) \equiv (\Omega_0, \Omega_1, \Omega_2) - (\Lambda_0, \Lambda_1, \Lambda_2)^{21}$$

$$h_0(\theta) \equiv \Omega_0 - \Lambda_0$$

$$h_1(\theta) \equiv \Omega_1 - \Lambda_1$$

$h_2(\theta) \equiv \Omega_2 - \Lambda_2$ Conditions for E-stability can be broken down by taking advantage of the fact that Ω_1 is a function of only Λ_1 :

$$\frac{\partial h_1}{\partial \Lambda_1^*} = (I \otimes C\Lambda_1^*) + (\Lambda_1^* \otimes C) + (\Lambda_1^{*2} \otimes D) + (\Lambda_1^* \otimes D\Lambda_1^*) + (I \otimes D\Lambda_1^{*2})$$

If the above Matrix given by the Gradient only contains Real Eigenvalues less than 1, then we can say that $\Lambda_1 \xrightarrow{inf} \Lambda_1^*$. Assuming this is satisfied, the next condition we must have is:

$$\frac{\partial h_0}{\partial \Lambda_0^*} = (I \otimes C) + (I \otimes C\Lambda_1^*) + (I \otimes D) + (I \otimes D\Lambda_1^*) + (\Lambda_1^* \otimes D\Lambda_1^*)$$

Similarly, If the real parts of the eigenvalues of the above equation are less than unity in absolute value, we can say: $\Lambda_0 \xrightarrow{inf} \Lambda_0^*$. The Last set of parameters in question are now Λ_2 :

²¹ $E[Q(\theta, Z_t, t)]$ is equivalent to the given condition of $h(\theta)$

$$\frac{\partial h_2}{\partial \Lambda_2^*} = (I \otimes C\Lambda_1^*) + (R \otimes I) + (I \otimes D\Lambda_1^{*2}) + (R \otimes D\Lambda_1^*) + (R^2 \otimes D)$$

If the real parts of the eigenvalues of the above equation are less than unity in absolute value, we can then say that the set of parameters satisfy the E-stability criterion.
